

1 Recap: Pseudorandom Generators

1. It is possible to construct a hard-core predicate for any one-way function. Let $f : \{0, 1\}^* \rightarrow \{0, 1\}^*$ be any one-way function (or permutation). We define $f'(r, x) = (r, f(x))$ for $|r| = |x|$. Then f' is also a one way function (or permutation, respectively), and $h(r, x) = \langle r, x \rangle \bmod 2$ is a hard core predicate for f' .
2. A pseudorandom generator exists under the assumption that a one-way permutation exists. Formally, if f is a OWP and h is a hard-core predicate for f , then $G(s) = (f(s), h(s))$ is a PRG with output length $\ell(n) = n + 1$.
3. If there exists a PRG $G(s) = (f(s), h(s))$ with output length $\ell(n) = n + 1$, then

$$G'(s) = (h(s), h(f(s)), h(f^{(2)}(s)), \dots, h(f^{(m-1)}(s)))$$

is a PRG of output length m for any $m = \text{poly}(|s|)$.

While it is well-known that the existence of a PRG implies that a OWF must exist, is the converse also true? That is, does the existence of a one-way function also imply that a pseudorandom generator must exist? In fact, this turns out to be true as well. Hastad, Impagliazzo, Levin, and Luby established in 1989 that a PRG can be constructed from any OWF. Their construction is much more complicated than the one for OWPs, because it must address the issue that the OWF f may be very “unstructured,” and thus the distribution of $f(x)$ may be very different from uniform, even when x is uniform. The HILL PRG construction utilizes a random seed of length n^{10} for a OWF of input length n . The details of the construction are beyond the scope of this class.

2 Pseudorandom Functions

2.1 Preliminary Concepts

Having already developed a precise definition for a pseudorandom *string* of bits, a natural extension is, what would a random *function* look like?

A function from $\{0, 1\}^n$ to $\{0, 1\}$ is given by specifying an output bit for every one of its inputs, of which there are 2^n . Therefore, the set of *all* functions from $\{0, 1\}^n$ to $\{0, 1\}$ contains exactly 2^{2^n} functions; a “random function” (with this domain and range) is a uniformly choice from this set. Such a function can also be viewed as a uniformly random 2^n -bit string, which simply lists all the function’s outputs. However, stated this way, it is impossible to even look at the entire string efficiently (in $\text{poly}(n)$ time). Therefore, we define a model in which we give *oracle* access to a function.

Writing \mathcal{A}^f signifies that \mathcal{A} has query access to f , i.e., \mathcal{A} can (adaptively) query the oracle on any input x and receive the output $f(x)$. However, \mathcal{A} only has a “black-box” (input/output) view of f , without any knowledge of how the function f is evaluated.

Definition 2.1 (Oracle indistinguishability). Let $\mathcal{O} = \{O_n\}$ and $\mathcal{O}' = \{O'_n\}$ be ensembles of probability distributions over functions from $\{0, 1\}^{\ell_1(n)}$ to $\{0, 1\}^{\ell_2(n)}$, for some $\ell_1(n), \ell_2(n) = \text{poly}(n)$. We say that $\mathcal{O} \stackrel{c}{\approx} \mathcal{O}'$ if, for all nuppt distinguishers \mathcal{D} ,

$$\text{Adv}_{\mathcal{O}, \mathcal{O}'}(\mathcal{D}) := \left| \Pr_{f \leftarrow O_n} [\mathcal{D}^f(1^n) = 1] - \Pr_{f \leftarrow O'_n} [\mathcal{D}^f(1^n) = 1] \right| = \text{negl}(n).$$

Naturally, we say that $\mathcal{O} = \{O_n\}$ is *pseudorandom* if

$$\mathcal{O} \stackrel{c}{\approx} \left\{ U \left(\{0, 1\}^{\ell_1(n)} \rightarrow \{0, 1\}^{\ell_2(n)} \right) \right\},$$

i.e., if no efficient adversary can distinguish (given only oracle access) between a function sampled according to O_n , and a uniformly random function, with more than negligible advantage.

Definition 2.2 (PRF Family). A family $\{f_s : \{0, 1\}^{\ell_1(n)} \rightarrow \{0, 1\}^{\ell_2(n)}\}_{s \in \{0, 1\}^n}$ is a *pseudorandom function family* if it is:

- *Efficiently computable*: there exists a deterministic polynomial-time algorithm F such that $F(s, x) = f_s(x)$ for all $s \in \{0, 1\}^n$ and $x \in \{0, 1\}^{\ell_1(n)}$.
- *Pseudorandom*: $\{U(\{f_s\})\}$ is pseudorandom.

Having developed a precise definition of a pseudorandom family of functions, the natural question arises: Does such a primitive even exist? And under what assumptions?

Notice that if $\ell_1(n) = O(\log n)$, all the output values of a function $f : \{0, 1\}^{\ell_1(n)} \rightarrow \{0, 1\}^{\ell_2(n)}$ can be written down as a string of exactly $2^{\ell_1(n)} \cdot \ell_2(n) = \text{poly}(n)$ bits. Moreover, all the function values can be queried in polynomial time, given oracle access. Therefore, a PRF family with $O(\log n)$ -length input may be seen as a PRG, and vice-versa. But do there exist PRF families with longer input lengths — say, n ?

Question 1. Let $\{f_s\}$ be a pseudorandom function family. Is the family $\{g_s\}$ where $g_s(x) = f_s(x) \parallel 0$ also pseudorandom?

2.2 Constructing PRFs

Theorem 2.3. *If a pseudorandom generator exists (i.e., if a one-way function exists), then a pseudorandom function family exists for any $\ell_1(n), \ell_2(n) = \text{poly}(n)$.*

At first glance, this theorem may seem completely absurd. The number of functions in the family $\{f_s\}$ with a seed length $|s| = n$ is at most 2^n , whereas the total number of functions overall (even with just one-bit outputs) is at least 2^{2^n} . Therefore, our function family is $\approx 2^{-2^n}$ -sparse, i.e., the family $\{f_s\}$ makes up only a *doubly exponentially* small subset of the entire space of functions.

Proof of Theorem 2.3. For simplicity, we prove the theorem for $\ell_1(n) = \ell_2(n) = n$; extending to other values is straightforward.

Our objective is to “stretch” an n -bit uniformly random string to produce an exponential (at least 2^n) number of “random-looking” strings. Assume without loss of generality that G is a PRG with output length $\ell(n) = 2n$. The basic idea is to view the output of G as two length- n pseudorandom strings, which can be used recursively as inputs to G to generate an exponential number of strings.

Formally, view G as a pair of length-preserving functions G_0, G_1 (i.e., $|G_0(s)| = |G_1(s)| = |s|$), where

$$G(s) = G_0(s) \parallel G_1(s).$$

The idea behind the PRF construction is that the function $f_s(x)$ computes a path, specified by the bits of x starting from the root seed s , as shown below:

It is easy to check that the simulator emulates the desired hybrids. First, if $(z_0, z_1) = (G_0(s), G_1(s))$ for $s \leftarrow U_n$, then $\mathcal{S}(z_0, z_1)$ answers each query $x \in \{0, 1\}^n$ as

$$G_{x_n}(\cdots G_{x_2}(G_{x_1}(s)) \cdots) = f_s(x),$$

exactly as in H_0 . Similarly, if $(z_0, z_1) \leftarrow (U_n, U_n)$, then \mathcal{S} answers each query exactly as in H_1 . Now because $G(U_n) \stackrel{c}{\approx} U_{2n}$ and \mathcal{S} is efficient, by the hybrid lemma we conclude that $H_0 \stackrel{c}{\approx} H_1$.

Unfortunately, this approach does not seem to scale too well when we go down to the deeper layers of the tree, because the simulator \mathcal{S} would need to take as input an exponential number of input strings. However, we can make two observations:

- In H_i , all the subtrees growing from the i th level are *symmetric*, i.e., they are identically distributed and independent.
- The polynomial-time distinguisher \mathcal{D} attacking the PRF can make only a *polynomial* number of queries to its oracle.

The key point is that the simulator then only needs to simulate $q(n) = \text{poly}(n)$ number of subtrees in order to answer all the queries of the distinguisher correctly.

For the hybrids H_{i-1} and H_i , Algorithm 1 defines a simulator that takes $q(n) = \text{poly}(n)$ pairs of n -bit strings.

Algorithm 1 Simulator \mathcal{S}_i for emulating either H_{i-1} or H_i .

Input: $(z_0^1, z_1^1), \dots, (z_0^q, z_1^q) \in \{0, 1\}^{2n}$ for some large enough $q(n) = \text{poly}(n)$

```

1:  $j \leftarrow 1$ 
2: while there is a query  $x \in \{0, 1\}^n$  to answer do
3:   if prefix  $x_1 \cdots x_i$  is not yet associated with any  $k$  then
4:     associate  $j$  to  $x_1 \cdots x_i$ 
5:      $j \leftarrow j + 1$ 
6:   end if
7:   look up the  $k$  associated with prefix  $x_1 \cdots x_i$ 
8:   answer  $G_{x_n}(\cdots G_{x_{i+1}}(z_{x_i}^k) \cdots)$ 
9: end while
```

We analyze the behavior of \mathcal{S}_i . Suppose that the distinguisher \mathcal{D} (making queries to \mathcal{S}_i) makes at most q queries, so the counter j never “overflows.” Now, if each of the pairs $(z_0^j, z_1^j) \leftarrow G(U_n^j)$ are independent pseudorandom strings, then \mathcal{S}_i answers each query x by $G_{x_n}(\cdots (G_{x_{i+1}}(G_{x_i}(U_n^k))) \cdots)$, for a distinct k associated uniquely with the i -bit prefix of x . By construction, \mathcal{S}_i therefore emulates H_{i-1} exactly. Similarly, if the $(z_0^j, z_1^j) \leftarrow U_{2n}^j$ are uniformly random and independent, then \mathcal{S}_i simulates H_i .

At this point, we would like to conclude that $H_{i-1} \stackrel{c}{\approx} H_i$, but can we? To do so using the hybrid lemma, we would need to show that the two types of inputs to \mathcal{S}_i (namely, a sequence of $q = \text{poly}(n)$ *independent pairs* (z_0, z_1) each drawn from either $G(U_n)$ or U_{2n}) are indistinguishable. This can be shown via a straightforward hybrid argument, using the hypothesis that G is a PRG, and is left as an exercise. \square

2.3 Consequences for (Un)Learnability

A family of functions is said to be *learnable* if any member of the family can be reconstructed efficiently (i.e., as code), given oracle access to the function. In this sense, a PRF family is *completely unlearnable*, in that no

efficient adversary can determine *anything* about the values of the function (given oracle access) on any of the unqueried points. As a consequence, if a class of functions is expressive enough to “contain” a PRF family, then this class is unlearnable. E.g., under standard assumptions, the class NC^1 can implement PRFs, hence it is unlearnable.

Answers

Question 1. Let $\{f_s\}$ be a pseudorandom function family. Is the family $\{g_s\}$ where $g_s(x) = f_s(x) \parallel 0$ also pseudorandom?

Answer. No. Intuitively, the output of g_s always ends in a 0, something which occurs only half the time in truly uniformly random strings. Concretely, an adversary simply choses an arbitrary string m , queries its oracle on m and returns 1 if the output ends in 0 and zero otherwise. When its oracle is g_s , the adversary always outputs 1 and when its oracle is a uniformly random function, it returns 1 with probability $\frac{1}{2}$. Hence, the adversary has a non-negligible advantage of $\frac{1}{2}$.
